## ABSTRACT

While early efforts to reduce external phosphorus (P) loads to Lake Erie eliminated the worst eutrophication symptoms in the 1970s and 1980s, the observed intensification of these symptoms in recent decades is difficult to explain by changes in the external P loading alone. We hypothesized that, in addition to external inputs, in-lake processes that release P to the water column may be contributing to the re-eutrophication of Lake Erie. Directly measuring these internal inputs is challenging and their scaling up to the entire lake system remains fraught with uncertainty. To constrain the magnitude of the net P input associated with in-lake processes, we generated a long-term annual total P (TP) budget for the Lake St. Clair–Lake Erie system, averaged over a 14-year period, from 2003 to 2016. The budget shows that the TP output from the system substantially exceeds the sum of the external TP inputs. To balance the budget, we estimate that in-lake processes add a net internal TP load of 3783 metric tons per year (MTA) to the water column. In comparison, the mean yearly external TP load to the Lake St. Clair–Lake Erie system is 11,703 MTA. Thus, overall, in-lake processes account for about a quarter of the total (external plus internal) TP input. The internal input is not evenly distributed among the system's basins, however, with Lake St. Clair and Lake Erie's western, central, and eastern basins receiving 6, 13, 21 and 60% of the total internal P input, respectively. Our results highlight the importance of accounting for the internal P loading in nutrient cycling modeling and load reduction strategies for large lake systems.

## 1. Introduction

The primary driver of cultural eutrophication is excess nutrient inputs from human activities. Management strategies aimed at mitigating the negative effects of lake eutrophication therefore focus on reducing external nutrient loads, with particular attention on phosphorus (P), the key macronutrient (co-)limiting primary production in aquatic ecosystems. Yet, many of these systems show increasing signs of eutrophication, even under stable or even reduced external loads. Examples range from small ponds to the coastal ocean (Fu et al., 2018), including estuaries and coastal bays (e.g., Chesapeake Bay: Najjar et al., 2010), enclosed and semi-enclosed seas (e.g., Baltic Sea: Munkes, 2005; Vahtera et al., 2007; Meier et al., 2011; Stigebrandt and Andersson, 2020), and lakes, such as Lake Winnipeg (Matisoff et al., 2017; Nürnberg and LaZerte, 2016), Lake of the Woods (Edlund et al., 2017; James, 2017), Lake Chaohu (Yang et al., 2020), and Lake Erie (Matisoff et al., 2016;

Scavia et al., 2014).

While early efforts to reduce external P loads to Lake Erie (IJC (International Joint Commission), 1978) initially eliminated the worst eutrophication symptoms, the lake has shown signs of re-eutrophication beginning in the late 1990s. In particular, since that time there have been more frequent and more severe cyanobacterial harmful algal blooms (HABs), expanded regions of bottom-water hypoxia, outbreaks of nuisance benthic green algae (e.g., *Cladophora glomerata*), and increased total phosphorus (TP) concentrations in the western and central basins (Rucinski et al., 2014; Scavia et al., 2014; Watson et al., 2016) compared to the 1980s and early to mid 1990s.

In addition to external P loads that are driven by on-land human activities and modulated by watershed hydrology and airshed transport, in-lake processes may also release P to the water column. This internally sourced P can be assimilated into the food web and contribute to eutrophication. In-lake mechanisms of P mobilization may be enhanced

by rising water temperature (Boström et al., 1982; Gomez et al., 1998; Jeppesen et al., 1997), photosynthetically driven pH increases (Sabur et al., 2021; Søndergaard et al., 2003; Welch and Cooke, 1995) in shallow environments characterized by dense cyanobacterial blooms (Chen et al., 2014, 2018; Zepernick et al., 2021), hypolimnetic hypoxia and anoxia (Nürnberg et al., 2019; Orihel et al., 2017; Welch and Cooke, 1995), salinization (Radosavljevic et al., 2022), and coastal sediment resuspension and shoreline erosion (Eadie et al., 1990, 2008; McKinney et al., 2019; Scavia et al., 2019a, 2019b, 2020). Despite growing evidence that these mechanisms can mobilize significant amounts of P (e.g., Nürnberg and LaZerte, 2016; Scavia et al., 2020), quantifying internal P loads in large lakes is difficult because the underlying mechanisms are generally highly dynamic in time and space.

Several studies have reported large internal P fluxes in Lake Erie (Matisoff et al., 2016; Paytan et al., 2017; Nürnberg et al., 2019; Gibbons and Bridgeman, 2020; Wang et al., 2021; Anderson et al., 2021; see Table A1: Tables, Figures and Appendices indexed with letters “A” and “B” can be found in corresponding Supporting Material A and B). For example, estimates for Lake Erie’s central basin as high as 11,000 metric tons per year (MTA) have been proposed (Anderson et al., 2021). However, the existing measurements cover limited spatial and temporal

scales, and may not be representative of the integrated long-term and basin-wide contribution of in-lake mobilization processes to the water column TP budget. While there is a general consensus that the re-trophication of the western basin of Lake Erie, including the recurrent HABs, is primarily driven by the external P loads, internal P loading may still play a role in modulating algal productivity, especially in years when the external P loading is relatively low (Matisoff et al., 2016). The magnitude of the internal P loading in the western basin, however, remains poorly constrained.

To assess the magnitudes of internal total P (TP) loads and compare them to external inputs, we constructed a 14-year average annual TP budget for Lake Erie. (Note: TP comprises all the P in a bulk water sample, including dissolved and particulate P, and both inorganic and organic forms of P). A multi-year averaging helps delineating the main features of elemental budgets of large lakes with relatively long water residence times (~2.8 years for Lake Erie; Bolsenga and Herdendorf, 1993). The difference between all external P inputs and all P outputs (including P accumulation in bottom sediments) then provides an estimate of the internal TP input (Orihel et al., 2017). The only assumption in this mass-balance approach is that the long-term TP budget is closed. It is important to note that, in and of itself, the approach does not

**Fig. 1.** Map of the Lake St. Clair-Lake Erie system with selected 36 major lake tributaries, locations of water quality monitoring stations along the connecting channels, and stations where precipitation is collected for water quality purposes. Tributaries are indicated by numbers corresponding to their names in Table 5. Area in green indicates the boundaries of the watershed area. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

identify which in-lake processes are responsible for the internal TP input. We apply the approach to Lake Erie because it has a well-documented history of cultural eutrophication and has extensive data on the external P inputs and in-lake water quality.

Lake Erie has three distinct basins (Fig. 1) with variable trophic states, morphometric properties, and thermal and mixing regimes, making them representative of a broader range of systems. Comparison of the budget calculations for the three basins may therefore yield insights into the role of internal P loading that are transferable across a range of large lake systems. Note that we include Lake St. Clair in our analysis because it is an integral part of Lake Erie’s watershed (Bolsenga and Herdendorf, 1993; Chapra et al., 2016) and represents a significant modifier of the P fluxes from Lake Huron to Lake Erie (Bocaniov et al., 2019; Scavia et al., 2019a, 2019b).

## 2. Methods and data sources

### 2.1. Study region

The Lake St. Clair–Lake Erie System is part of the Laurentian Great Lakes–St. Lawrence River drainage system in the upper mid-west of North America. It is located between Lake Huron and Lake Ontario (Fig. 1) and consists of the Huron-Erie Corridor (HEC: St. Clair River, Lake St. Clair, and Detroit River) and Lake Erie proper. In addition to its own watershed, HEC receives water and accompanying chemical loads from Lake Huron. Lake St. Clair is a relatively large, shallow, oligomesotrophic, polymictic lake (mean depth = 3.8 m; maximum natural depth = 6.4 m; Bocaniov and Scavia, 2018; Bocaniov et al., 2019). It is connected to Lake Huron via the St. Clair River and flows into the Detroit River that, in turn, flows into the western basin of Lake Erie. Note that the St. Clair River and Detroit River are connecting channels rather than actual rivers (Bolsenga and Herdendorf, 1993).

Lake Erie itself is a large, relatively shallow lake separated topographically into three basins with distinct morphometric characteristics, mixing regimes, and trophic conditions (Bolsenga and Herdendorf, 1993). The western and eastern basins are the most and least productive, respectively. The western basin is the shallowest (mean and maximum depths: 7.3 and 19 m), characterized by a prevailing polymictic mixing regime, but with short episodes of hypoxia in summer (Jabbari et al., 2019), and dense cyanobacterial blooms towards the end of summer and early fall (Sayers et al., 2019). It is separated from the central basin by a chain of rocky islands and shoals (Fig. 1). The central basin is dimictic (mean and maximum depths: 18.3 and 26 m) and deep enough to stratify vertically from mid-June to mid-late October with an hypolimnion susceptible to seasonal hypoxia. The eastern basin is the deepest (mean and maximum depths: 24 and 63 m) with the second largest volume and surface area. The major outflow from Lake Erie is through the Niagara River, the channel connecting Lake Erie to Lake Ontario, and the Well-and Canal (Fig. 1). The latter was built to bypass the Niagara Falls and provide a deep draft navigation connection between the two lakes.

### 2.2. Lake segmentation and watershed delineation

The Lake St. Clair–Lake Erie system was divided into the following segments along with their corresponding watersheds: St. Clair River, Lake St. Clair, and Detroit River, plus Lake Erie’s western, central, and eastern basins. Delineation of the Canadian sub-watersheds (Table A2 and Fig. A1) was based on the tertiary and quaternary sub-watersheds identified in the Ontario Watershed Boundaries dataset (ODC, 2019). Delineation of the United States sub-watersheds (Table A3; Fig. A1) was based on the U.S. Geological Survey (USGS) 6-digit and 8-digit hydrologic unit codes (HUC6, HUC8) in the U.S. Watershed Boundary Dataset (WBD, 2019). Together, this yielded 67 Canadian and 28 U.S. sub-watersheds (Tables A2 & A3) that include not only the major river tributaries flowing into the St. Clair River, Lake St. Clair, the Detroit River, and Lake Erie, but also the smaller, nearshore watersheds with direct

drainage to the different lake segments.

### 2.3. Long-term budgets: Approach

We constructed long-term, post-2000 water and TP mass balances (Table 1: Eqs. 1–6 for water and 7–12 for TP; see Table 2 for definitions of the symbols in the equations) for the four major segments of the Lake St. Clair–Lake Erie system by averaging data of 14 water years, from October 1, 2002, to September 30, 2016. For each segment, the water cycle was assumed to be closed, with inflows and over-lake precipitation equal to outflows and evaporation, plus or minus the change in water volume. The (unknown) in-lake TP loading fluxes ( $L_i$ ) were obtained for each segment by solving Eqs. 8 and 10–12 (Table 1) assuming steady state conditions ( $dp/dt = 0$ , with  $p$  representing the TP concentration). In preliminary work, we performed non-steady state calculations (i.e.,  $dp/dt \neq 0$ ) where we incorporated the observed temporal trends in TP concentration over the study period. These calculations, however, produced results very close to those of the steady state calculations (Table A1). Data sources for the water and TP balances are provided in Tables A4 to A9. The following two sub-sections describe how the various terms in the water and TP mass balance equations were estimated. Further details can be found in Appendices A2 to A7.

**Table 1**

Mass balance equations for calculating the mean annual water and TP mass balances (with eqs. 7–12 modified after Chapra et al., 2016) averaged over the 2003–2016 period. See Table 2 for the definitions of the symbols.

Segment	Equation	Eq. #
<i>Segment-specific water mass budgets:</i>		
St. Clair River	$Q_{scr,ds} = Q_{scr,us} + R_{scr}$	(1)
Lake St. Clair	$Y_s + R_s + Q_{scr,ds} + Q_{HWTP} + Q_s^{gw} = E_s + Q_{dr,us} + \Delta V_s + CU_s$	(2)
Detroit River	$Q_{dr,ds} = Q_{dr,us} + R_{dr}$	(3)
Western Basin (Lake Erie)	$Y_w + R_w + Q_{dr,ds} + Q_w^{gw} = E_w + Q_w + \Delta V_w + CU_w$	(4)
Central Basin (Lake Erie)	$Y_c + R_c + Q_w + Q_c^{gw} = E_c + Q_c + \Delta V_c + CU_c$	(5)
Eastern Basin (Lake Erie)	$Y_e + R_e + Q_c + Q_e^{gw} = E_e + Q_{nr,us} + Q_{wc,us} + \Delta V_e + CU_e$	(6)
<i>Segment-specific phosphorus mass budgets:</i>		
St. Clair River	$W_{scr}^T = Q_{scr,us} \cdot p_{LH} + W_{scr}^R = Q_{dr,ds} \cdot p_{dr,ds}$	(7)
Lake St. Clair	$V_s \frac{dp_s}{dt} = W_{scr}^T + W_s^R - Q_{dr,us} \cdot p_s - v_s \cdot A_s \cdot p_s - \Delta V_s \cdot p_s - CU_s \cdot p_s + Y_s \cdot p_s^{PR} \cdot k + Q_s^{gw} \cdot p^{gw} + L_s$	(8)
Detroit River	$W_{dr}^T = Q_{dr,us} \cdot p_s + W_{dr}^R = Q_{dr,ds} \cdot p_{dr,ds}$	(9)
Western Basin (Lake Erie)	$V_w \frac{dp_w}{dt} = W_{dr}^T + W_w^R - Q_w \cdot p_w + E'_{w/c} (p_c - p_w) - v_w \cdot A_w \cdot p_w - \Delta V_w \cdot p_w - CU_w \cdot p_w + Y_{LE} \cdot p_{LE}^{PR} \cdot k \cdot a_w + Q_w^{gw} \cdot p^{gw} + L_w$	(10)
Central Basin (Lake Erie)	$V_c \frac{dp_c}{dt} = Q_w \cdot p_w + W_c^R - Q_c \cdot p_c + E'_{w/c} (p_w - p_c) + E'_{c/e} (p_e - p_c) - v_c \cdot A_c \cdot p_c - \Delta V_c \cdot p_c - CU_c \cdot p_c + Y_{LE} \cdot p_{LE}^{PR} \cdot k \cdot a_c + Q_c^{gw} \cdot p^{gw} + L_c$	(11)
Eastern Basin (Lake Erie)	$V_e \frac{dp_e}{dt} = Q_c \cdot p_c + W_e^R - (Q_{nr} + Q_{wc}) \cdot p_{nr} + E'_{c/e} \cdot (p_c - p_e) - v_e \cdot A_e \cdot p_e - \Delta V_e \cdot p_e - CU_e \cdot p_e + Y_{LE} \cdot p_{LE}^{PR} \cdot k \cdot a_e + Q_e^{gw} \cdot p^{gw} + L_e$	(12)

Note: Eqs. 8 and 10 to 12 can be solved at steady state (i.e., all  $dp/dt = 0$ ) and at non-steady state ( $dp/dt \neq 0$ ). In both cases, these equations form linear algebraic systems with only one unknown, that is, the internal load ( $L$ ).

**Table 2**

Definitions of abbreviations, variables, and parameters in the water and phosphorus mass balance equations shown in Table 1.

#	Term	Explanation
1	TP	Total phosphorus
2	<i>s, w, c, e</i>	Abbreviations for Lake St. Clair ( <i>s</i> ), Western Basin ( <i>w</i> ), Central Basin ( <i>c</i> ), and Eastern Basin ( <i>e</i> )
3	<i>scr, dr, nr</i>	Abbreviations for the St. Clair River ( <i>scr</i> ), Detroit River ( <i>dr</i> ), and Niagara River ( <i>nr</i> )
4	<i>gw, wc, LH, LE</i>	Abbreviations for ground water ( <i>gw</i> ), Welland Canal ( <i>wc</i> ), Lake Huron ( <i>LH</i> ), and Lake Erie ( <i>LE</i> )
5	<i>HWTP</i>	Huron water treatment plant
6	<i>us, ds</i>	Upstream location ( <i>us</i> ), downstream location ( <i>ds</i> )
7	$Y_i, E_i$	Over-water precipitation ( $Y_i$ ) and over-water evaporation ( $E_i$ ) for segment $i$ ( $\text{km}^3 \text{yr}^{-1}$ )
8	$R_i$	Total watershed outflow reaching segment $i$ ( $\text{km}^3 \text{yr}^{-1}$ )
9	$i$	Segment index
10	$Q_i$	Advective outflow from segment $i$ ( $\text{km}^3 \text{yr}^{-1}$ )
11	$Q_i^{gw}$	Ground water discharge into segment $i$ ( $\text{km}^3 \text{yr}^{-1}$ )
12	$W_i^T, W_i^R$	Direct mass loading of total phosphorus (MTA) to segment $i$ with subscript $T$ representing inflow plus total watershed inputs, and subscript $R$ representing total watershed inputs
13	$A_i$	Surface area ( $\text{km}^2$ ) for segment $i$ : $A_s = 1114$ ; $A_w = 3284$ ; $A_c = 16,138$ ; $A_e = 6235$
14	$E'_{w/c}, E'_{c/e}$	Bulk dispersion coefficient for turbulent transport ( $\text{km}^3 \text{yr}^{-1}$ ) between Lake Erie basins (Chapra et al., 2016): $E'_{w/c} = 22.1$ and $E'_{c/e} = 197.5$
15	$V_b$	Volume of segment $i$ ( $\text{km}^3$ )
16	$\Delta V_i$	Rate of change in volume ( $\Delta V_i$ ) obtained from the difference in volume $i$ between time $t$ and $t = 0$ for segment $i$ ( $\text{km}^3 \text{yr}^{-1}$ )
17	$p_i$	TP concentration ( $\mu\text{g L}^{-1}$ or $\text{mg m}^{-3}$ ) in segment $i$
18	$p^{gw}$	Median TP concentration in groundwater: $p^{gw} = 20 \mu\text{g L}^{-1}$ (Table 9)
19	$p_i^{PR}$	Estimated volume weighted mean concentration of TP in precipitation for segment $i$ (Appendix A5; Table A10)
20	$CU_i$	Consumptive water use in segment $i$ ( $\text{km}^3 \text{yr}^{-1}$ )
21	$v_i$	Apparent settling velocity of TP ( $\text{m yr}^{-1}$ ) in segment $i$ : $v_s = 50$ ; $v_w = 50$ ; $v_c = 30$ ; $v_e = 32$ (Chapra et al., 2016)
22	$L_i$	Internal TP load (MTA) required to balance inputs and outputs for segment $i$
23	$k$	Coefficient to compute total (wet and dry) TP deposition from wet deposition; $k = 3.45$ (Anderson and Downing, 2006)
24	$a_i$	Area of segment $i$ as a proportion of total Lake Erie surface area: $a_w = 0.128$ ; $a_c = 0.629$ ; $a_e = 0.243$ (Table 4)
25	MTA	Metric tons per year

## 2.4. Water budgets

The annual volumes and water inputs and outputs for all the lake segments were estimated for each of the 14 water years, and then averaged to construct the average water budgets for Lake St. Clair and Lake Erie. Where required, minor adjustments were made to close the water budgets (Appendix A3). Next, the closed water budget of Lake Erie was further divided into the three, western, central, and eastern basin-specific water budgets (Eqs. 4–6; Table 1).

Annual volumes and surface areas of the Lake St. Clair–Lake Erie segments were derived from the lake bathymetry (NOAA, 2020a) and water levels (Table A5). The latter were estimated from the mean daily water levels measured at multiple locations with gauges operated by Canada's Department of Fisheries and Oceans (DFO, 2020) and the United States National Oceanic and Atmospheric Administration (NOAA, 2020b). Annual net changes in storage of Lake St. Clair and Lake Erie were calculated as the product of the measured changes in lake stage times the lake surface area. For the St. Clair River and Detroit River connecting channels, the annual volume was calculated as the product of the mean annual flow and the reported literature value of the water storage capacity (0.88 days for the St. Clair River, Griffiths et al., 1991; 0.83 days for the Detroit River, Derecki, 1984). The approximation of a constant storage capacity for the connecting channels introduced negligible errors in the much larger Lake St. Clair and Lake Erie water budgets.

Monthly over-lake precipitation and evaporation data were obtained from the NOAA Great Lakes Environmental Research Laboratory Hydrologic Data base (GLERL, 2020a). For Lake Erie's three basins, precipitation and evaporation rates were prorated using the ratios of the basin surface areas to the total lake area. Daily flow rates for the major tributaries were downloaded from the USGS National Water Information System (USGS, 2019) and the National Water Data Archive HYDAT (HYDAT, 2020) for sites in the United States and Canada, respectively (Tables A4 & A5). For rivers with multiple flow gauges, area-weighted estimates of flow at the downstream confluence were used. The flow data were scaled up to the corresponding entire sub-watershed areas to account for the unmonitored area runoff (Tables A2 & A3).

The annual direct groundwater inflow to Lake Erie ( $11.9 \text{ m}^3 \text{ s}^{-1}$ ) was derived from integrated surface water-groundwater modeling results (Xu et al., 2021). To estimate the groundwater flux to an individual lake segment, the total groundwater inflow was prorated using the ratio of the segment's water surface area to the total water surface assuming  $0.5 \text{ m}^3 \text{ s}^{-1}$  for Lake St. Clair and  $11.5 \text{ m}^3 \text{ s}^{-1}$  for Lake Erie. For Lake Erie this yielded 1.5, 7.2 and  $2.8 \text{ m}^3 \text{ s}^{-1}$  for the western, central, and eastern basin, respectively. The two major water diversions considered were the Welland Canal (Fig. 1), which moves water from Lake Erie's eastern basin to Lake Ontario, and the Detroit public water intake, which transfers Lake Huron water to the water supply system that subsequently returns it to Lake St. Clair (average daily flow of  $7.0 \text{ m}^3 \text{ s}^{-1}$ , 2003 to 2015 data: DWSD, 2019). Consumptive water usage was obtained from the Great Lakes Regional Water Use Database (GLC, 2019).

## 2.5. Total phosphorus (TP) budgets

For each lake and connecting channel segment, annual TP water column standing stocks, inputs, and outputs were estimated and then averaged over the 14 water years. The estimates combined water column volumes and water fluxes from the water budgets with mean TP concentrations in water columns, tributaries, and other input and output pathways. To estimate the removal of TP from the water column by sediment deposition at the lake floor, we used the apparent settling velocities reported by Chapra et al. (2016). These authors provide a detailed discussion of these rates, including their spatial and historical (pre-vs. post-1990) variability, and the possible reasons for their variability. Inter-basin TP exchanges in Lake Erie were separated between advective and dispersive fluxes, where the latter fluxes were estimated based on average annual TP concentration differences between adjacent basins and reported bulk dispersion coefficients for turbulent transport between basins (Tables 1 and 2). For Lake Erie, the TP mass balance was first developed for the entire lake and then the estimated inter-basin P exchanges were used to split the whole-lake TP budget into the three basin-specific budgets.

Lake Erie TP concentrations were extracted from the U.S. Environmental Protection Agency (USEPA) Great Lakes National Program Office (GLNPO, 2020), which conducts two lake-wide offshore monitoring cruises each year to characterize both the well-mixed spring (early April) and stratified summer (August) conditions, with 6, 10 and 4 sampling stations in the western, central, and eastern basins, respectively. Similar to previous studies (e.g., Chapra et al., 2016), representative annual basin-specific concentrations were obtained by averaging the spring and summer median values to make the results less sensitive to the outliers. Because there are no systematic in-lake monitoring data of TP concentrations in Lake St. Clair, the TP concentrations measured in the lake outflow (USEPA station #820017; Fig. 1) were used to represent in-lake concentrations. This is justified by Lake St. Clair's short hydraulic residence time ( $\sim 10$  days; Bocaniov and Scavia, 2018).

For any given water year, the TP standing stock in each of Lake Erie's basins was estimated as the product of the basin water volume times the mean basin-specific TP concentration for that year. For Lake St. Clair, the annual TP standing stocks were calculated as the lake's annual water volume times the mean annual concentration in the lake's outflow to the

Detroit River. Annual standing stocks of TP of the St. Clair River and Detroit River channels were calculated by dividing the mean annual TP load to the channel by the flushing rate, where the latter is equal to the ratio of the mean annual water discharge divided by the channel volume. The TP removal via consumptive water use was calculated as the annual rate of consumptive water use multiplied by the basin-specific average annual TP concentration. TP loss due to changes in lake storage was estimated as the annual rate of change of the volume multiplied by the corresponding basin-specific average annual TP concentration.

Data on TP concentrations in inflows and outflows were extracted from multiple sources, including the United States Water Quality Portal (WQP, 2019), National Center for Water Quality Research at Heidelberg University, Ohio (NCWQR, 2020), Michigan Department of Environmental Quality (MDEQ), Provincial (Stream) Water Quality Monitoring Network (PWQMN, 2019), Ontario Provincial Groundwater Monitoring Network (PGMN, 2022), Great Lakes Intake Program (GLIP, 2019) managed by the Ontario Ministry of the Environment, Conservation and Parks (MECP), and Environment and Climate Change Canada (ECCC).

All tributary TP loads were estimated with the Weighted Regression on Time, Discharge, and Season (WRTDS) method (Hirsch et al., 2010) using reported concentrations and flow data. The WRTDS method, however, could not be applied to the three connecting channels (St. Clair River, Detroit River, and Niagara River) because the TP concentrations and discharge flows are not correlated. Following Scavia et al. (2019a, 2019b), we therefore used the Generalized Additive Model (GAM, Wood, 2011, 2017) to approximate daily TP concentrations as a function of time, with the smoothing parameters selected with the Restricted Maximum Likelihood (REML) method. The estimated daily TP concentrations and standard errors were multiplied by the corresponding daily discharge flows to estimate daily TP fluxes and the associated uncertainties. The daily estimates were then summed to generate annual fluxes.

We applied GAM to calculate the TP loads at the inflow and outflow locations of the St. Clair River and the inflow locations of the Detroit River and Niagara River. As both flow and TP concentrations in the downstream portion of the Detroit River are affected by water level fluctuations in the western basin of Lake Erie due to surface seiches, wind-driven water set-ups, and corresponding backflow, the annual TP load delivered by the Detroit River to the western basin of Lake Erie was estimated as the sum of the TP inflow flux from Lake St. Clair (21MICH-820,414; Table A7) plus the added TP loads from all the Detroit River's sub-watersheds. The TP outflow flux via the Niagara River was estimated with GAM using gauged flow data and river TP concentrations measured at ECCC's Fort Erie station (Fig. 1). Due to its proximity to the Niagara River, the Welland Canal's TP outflow flux was estimated by multiplying the reported daily canal water discharge by the same mean daily TP concentration as for the Niagara River.

The estimates of tributary point source loads reported here correspond to direct inputs downstream of the last monitoring station along a river course (Maccoux et al., 2016; Scavia et al., 2019a, 2019b); any upstream point source would have been captured by the monitoring data. The TP concentrations associated with direct groundwater inputs to Lake Erie were assumed equal to the median long-term TP concentrations observed in groundwater monitoring wells located within 8 km of the shoreline, which represents the zone where most lake water-ground water exchanges occur in the Laurentian Great Lakes (Xu et al., 2021). On the Canadian side of Lake Erie, TP concentration data are measured at 19 such groundwater monitoring wells covering all three basins (Table A9). Similar data, however, are not available for the United States side of Lake Erie (USGS, 2022). In addition, the Canadian groundwater TP concentrations are only analyzed once a year. Therefore, we decided to pool all of the available data from 2002 to 2019 to derive a single TP median concentration value that was then systematically applied over the entire study period.

Over-lake atmospheric wet TP deposition was calculated as the product of the volume-weighted mean rainwater TP concentration ( $p^{PR}$ )

and the amount of precipitation. The  $p^{PR}$  values were based on data from three ECCC wet precipitation gauges located on the east shore of Lake St. Clair and, for Lake Erie, at Point Pelee and Rock Point (Fig. 1; Appendix A5). The stations' location coordinates and sampling methods are described in Chan et al. (2003), and the concentrations are reported by ECCC's Water Quality Monitoring and Surveillance Division (WQMSD, 2019). The over-lake precipitation rates used were those given in GLERL (2020b). Total (wet plus dry) over-lake TP deposition was estimated using the average wet and dry TP deposition ratio for the continental United States (Anderson and Downing, 2006).

Annual net TP sediment deposition rates for each of the three Lake Erie basins and Lake St. Clair were calculated using the post-1990 settling velocities of Chapra et al. (2016), the mean basin-specific TP concentrations and the corresponding lake bottom areas. The settling velocities reported by Chapra and coworkers in previous Lake Erie TP mass balance modeling are apparent parameters that were calibrated to reproduce observed average open lake concentrations (Chapra et al., 2016; Chapra and Dolan, 2012). As such, the effects of post-depositional processes at the lake floor, including recycling of P from the sediments back to the water column, are folded into the parameter values. In turn, this implies that using these apparent velocities should yield lower limits for our mass balance-derived internal P loads. As discussed further below, we speculate that our relatively large internal load estimates must in part reflect in-lake TP remobilization processes other than the classical, redox-dependent efflux of dissolved P from the lake floor, as already suggested by Chapra and Dolan (2012) and Chapra et al. (2016). It is useful to note that the apparent settling velocities used in estimating the internal TP loads in Lake Erie are in general agreement with the relatively sparse direct field-based measurements (Bloesch, 1982), as well as with the typical range of sedimentation rates of fine-grained sediments (Kemp et al., 1977; Mortimer, 1987) together with reported sediment TP concentrations in depositional areas of the Lake Erie basins (Williams et al., 1976; see Appendix A6 for further details).

The inter-basin TP exchanges in Lake Erie were calculated with the bulk horizontal eddy diffusion coefficients reported in Chapra et al. (2016) multiplied by the differences in the mean annual basin-specific TP concentrations between adjacent basins. Finally, the internal TP loads to the water column of Lake St. Clair and Lake Erie's basins that are mobilized by in-lake processes were determined as the differences between all the estimated external inputs and outputs averaged over the 14-year study period.

## 2.6. TP relative residence times

The TP relative residence time is a useful parameter to gauge the sensitivity of TP concentrations to in-lake processing (Janus and Volenweider, 1984; Sonzogni et al., 1976). It equals the ratio of the mean TP residence time ( $R_p$ ; yr) to the mean water residence time ( $R_w$ ; yr). Using the water and TP budgets, we computed  $R_w$  and  $R_p$  for Lake Erie, its three basins, and Lake St. Clair:  $R_w$  was calculated as the ratio of the mean annual water volume (in  $\text{km}^3$ ) to mean annual water supply (in  $\text{km}^3 \text{yr}^{-1}$ ), while  $R_p$  was calculated as the mean annual standing stock of TP in the water column divided by annual external TP supply. For the St. Clair River and the Detroit River, literature values of  $R_w$  were used: 0.88 days for St. Clair River (Griffiths et al., 1991) and 0.83 days for Detroit River (Derecki, 1984).

## 3. Results

### 3.1. Watershed delineation

The entire Lake St. Clair-Lake Erie drainage basin (77,213  $\text{km}^2$ ) comprises two sub-basins: the 17,711  $\text{km}^2$  Huron Erie Corridor (HEC) watershed and Lake Erie's 59,501  $\text{km}^2$  direct watershed (Table 3; Fig. 2a). HEC includes the watersheds of Lake St. Clair (69% or 12,226  $\text{km}^2$ ), the Detroit River (11% or 1986  $\text{km}^2$ ), and the St. Clair River (20%

**Table 3**  
Watershed areas (km<sup>2</sup>) of the Lake St. Clair-Lake Erie system.

#	System	Total Area (TA)			Monitored Area (MA)			MA as % of TA [%]		
		Canada	USA	Total	Canada	USA	Total	Canada	USA	Total
1	HEC, including:	10,469	7242	17,711	6854	4936	11,790	65.5	68.2	66.6
1.1	St. Clair River	502	2997	3499	0	2031	2031	0.0	67.8	58.0
1.2	Lake St. Clair	9499	2727	12,226	6625	1901	8526	69.7	69.7	69.7
1.3	Detroit River	468	1518	1986	229	1005	1234	48.9	66.2	62.1
2	LE, including:	12,174	47,327	59,501	8724	36,594	45,318	70.4	77.3	75.9
2.1	West Basin	431	26,467	26,898	0	22,742	22,742	0.0	85.9	84.5

	Total (HEC + LE)	22,643	54,570	77,213	15,424	41,531	56,955	68.1	76.1	73.8

Abbreviations: Huron-Erie Corridor (HEC), Lake Erie (LE), watershed area (WA).

or 3499 km<sup>2</sup>). The watersheds of Lake Erie's three basins include the western basin (45% or 26,898 km<sup>2</sup>), central basin (29% or 17,474 km<sup>2</sup>), and eastern basin (26% 15,129 km<sup>2</sup>). The total area covered by hydrological and water quality data represents 74% of the total Lake Erie drainage basin (Table 3). While the Canadian portion of the HEC watershed is larger than the US portion (59% versus 41%), the US portion of the Lake Erie watershed is the largest at about 80% (Table 3; Fig. 2a).

### 3.2. Mean annual water budgets (2003 to 2016)

The volumes of Lake St. Clair and Lake Erie, averaged over the 14-year period, were 4.6 and 501.0 km<sup>3</sup> (Table 4). Lake Erie's total volume was divided into the western (5.4% or 27.2 km<sup>3</sup>), central (63.0% or 315.5 km<sup>3</sup>), and eastern (31.6% or 158.1 km<sup>3</sup>) basins. The mean volumes of the St. Clair River and Detroit River channels were about 0.4 km<sup>3</sup> each (Table 4). The surface area of Lake St. Clair was estimated at 1114 km<sup>2</sup>, that of Lake Erie's at 25,657 km<sup>2</sup> (Table 4). Lake Erie's basin surface areas were 3284 km<sup>2</sup>, 16,138 km<sup>2</sup>, and 6235 km<sup>2</sup> for the western, central, and eastern basins, respectively.

Although there are many tributaries to the Lake St. Clair-Lake Erie system (Fig. 1; Table 5) their flow contributions are relatively small compared to the flow rates of the connecting channels. The St. Clair River flow averaged 5042 and 5068 m<sup>3</sup> s<sup>-1</sup> at the channel's inlet and mouth (Tables 6, 7, B1 to B4; Fig. 2b), respectively. Lake St. Clair added only 2.8% to the inflow from the St. Clair River, yielding an outflow to the Detroit River of 5212 m<sup>3</sup> s<sup>-1</sup>. The Detroit River flow increased by 23 m<sup>3</sup> s<sup>-1</sup> to 5235 m<sup>3</sup> s<sup>-1</sup> at the outflow into the western basin of Lake Erie. Lake Erie's direct watersheds added 13.4% to the Detroit River flow for a total Lake Erie outflow of 5935 m<sup>3</sup> s<sup>-1</sup> divided between the Niagara River (96.7% or 5740.2 m<sup>3</sup> s<sup>-1</sup>) and the Welland Canal (3.3% or 194.5 m<sup>3</sup> s<sup>-1</sup>). Watershed inflows to Lake St. Clair and Lake Erie were estimated at 142 and 799 m<sup>3</sup> s<sup>-1</sup>, respectively.

On average, over-lake evaporation (31 and 716 m<sup>3</sup> s<sup>-1</sup>) exceeded precipitation (27 and 651 m<sup>3</sup> s<sup>-1</sup>) by about 15% and 10% in Lake St. Clair and Lake Erie, respectively (Tables 6, 7, B1 to B4; Fig. 2b-c). Consumptive water usage was very small (<0.5% of total lake inflow) with a mean value of 23.5 m<sup>3</sup> s<sup>-1</sup>. The net losses in lake storage were minor for both Lake St. Clair and Lake Erie (1.4 and 21.5 m<sup>3</sup> s<sup>-1</sup>, respectively), or <0.03% and 0.4% of the lakes' outflows. Diversions from Lake Huron by the Detroit Water Treatment Plant (Huron WTP) and groundwater recharge were the smallest fluxes, accounting for 7 m<sup>3</sup> s<sup>-1</sup> and 12 m<sup>3</sup> s<sup>-1</sup>, respectively.

### 3.3. Mean annual TP mass budget (2003 to 2016)

Lake Erie's TP standing stock (5012 MT, Table 4) was equivalent to 45% of the lake's yearly external input of TP (11,116 MTA; see Figs. 3 & 4; Table 8). The TP standing stocks of the western, central, and eastern basins were 540 MT, 3311 MT, and 1161 MT, respectively. Lake St. Clair had a standing stock of 69 MT, and the St. Clair River and Detroit River

channels had standing stocks of 5 and 7 MT, respectively (Table 4).

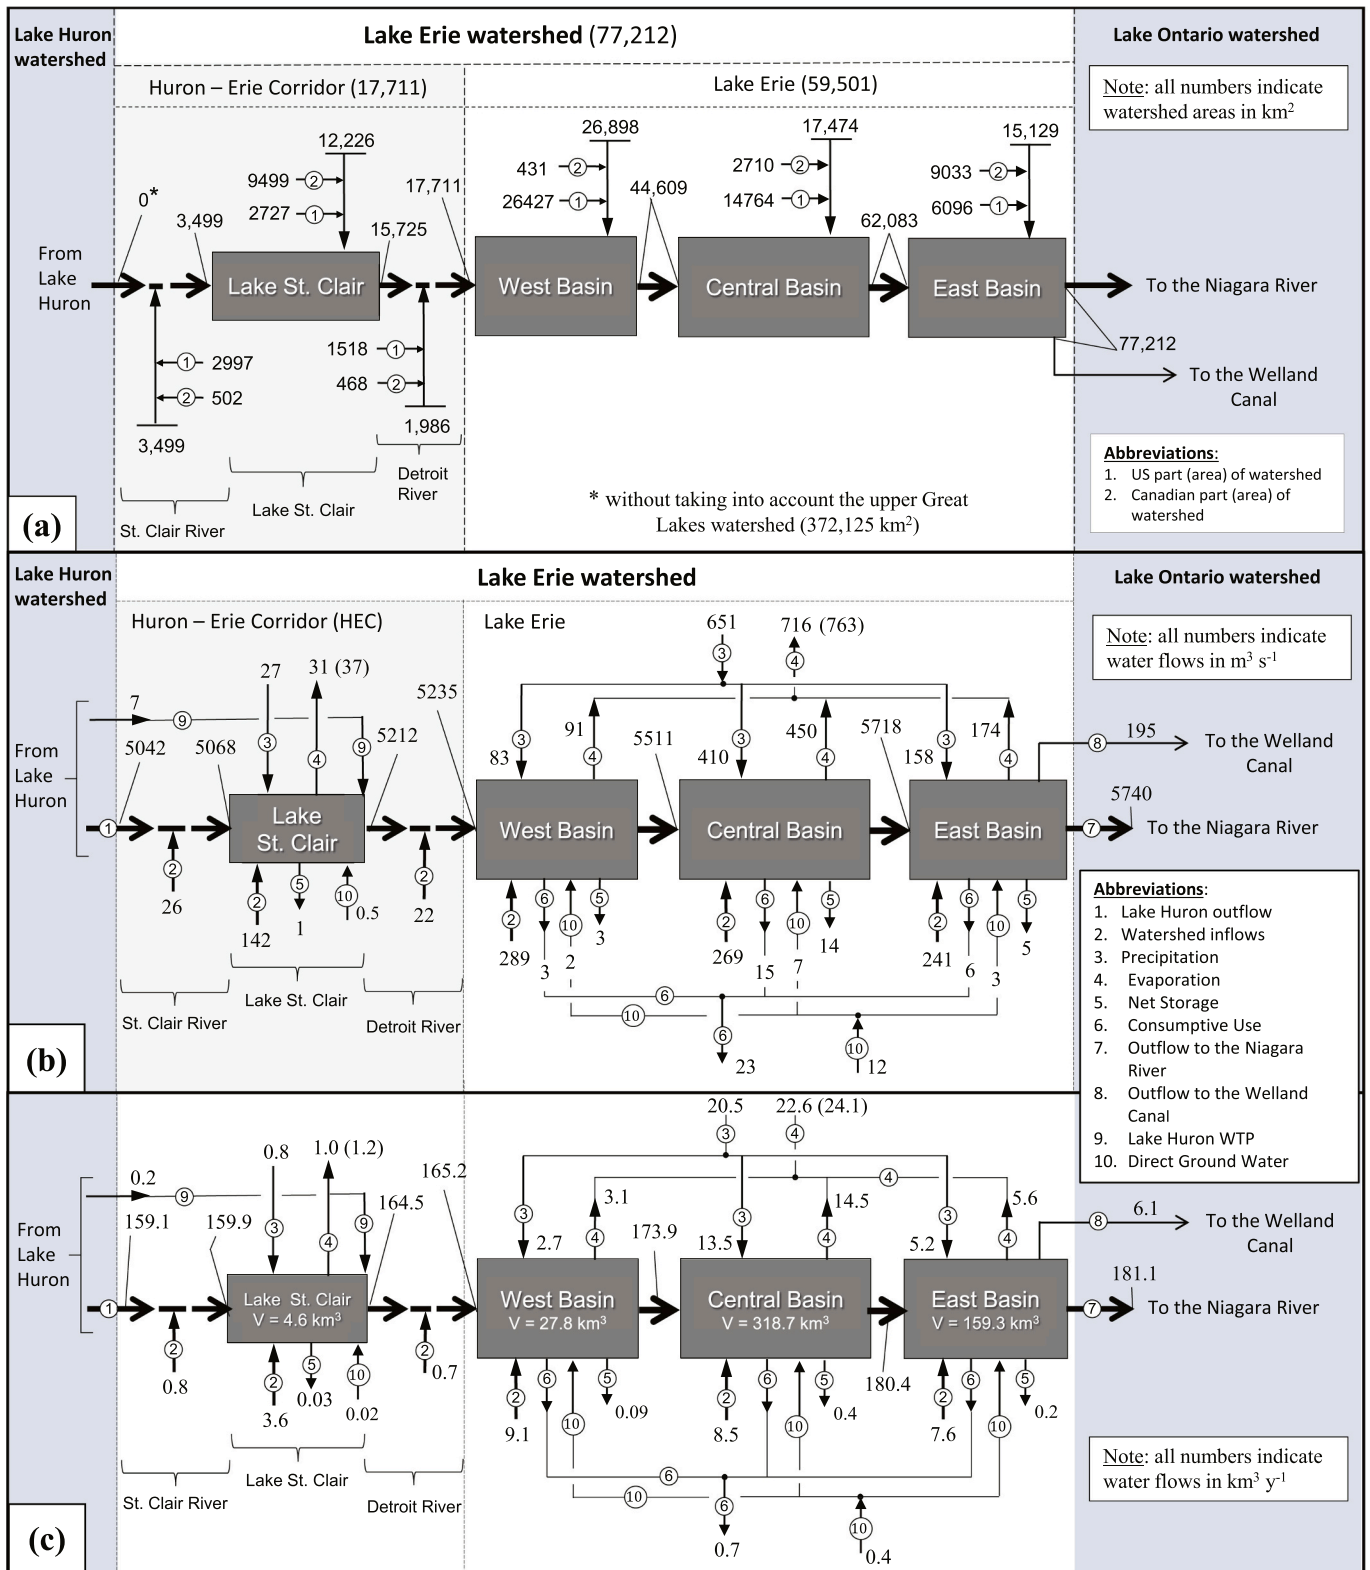

The mean atmospheric deposition of TP (Table A10) ranged from 52 MTA for Lake St. Clair to 992 MTA for Lake Erie, with 127 MTA, 624 MTA and 241 MTA for the western, central, and eastern basins, respectively (Fig. 3a-b; Tables 8, B7, B9 to B11). The over-lake atmospheric TP loading represented <10% of the total external load for the entire Lake St. Clair-Lake Erie system (1044 versus 11,703 MTA; Table 8). Fluxes associated with changes in lake volume, consumptive use, and ground water were all less important (Fig. 3). The median groundwater TP concentration was about 20 mg P m<sup>-3</sup> (Table 9).

The largest external TP input to the Lake St. Clair-Lake Erie system (8797 MTA) originated from the direct watersheds, with 3020 MTA, 2538 MTA, and 1455 MTA inputs to the western, central, and eastern basins, respectively, 911 MTA to Lake St. Clair; and 208 MTA and 665 MTA to the St. Clair River and Detroit River, respectively (Table 8). The mean input flux of TP from Lake Huron to the St. Clair River was 1862 MTA (Fig. 3a; Tables 6, 8, B6) and included 1100 MTA derived using the monitoring data for the inflow from Lake Huron to the St. Clair River plus an estimated 762 MTA generated by episodic events of coastal erosion and resuspension that are not captured by the monitoring data (Scavia et al., 2019a, 2019b, 2020, 2022). Including contributions from the St. Clair River watershed (208 MTA), the total load delivered by the St. Clair River to Lake St. Clair was then 2070 MTA.

The largest tributary to Lake St. Clair in terms of TP load was the Thames River with a mean annual load of 429 MTA followed by the Sydenham and Clinton rivers (170 and 145 MTA, respectively; Fig. 1; Table 5). For Lake Erie, the Maumee River was by far the most significant source of TP to the lake delivering alone a mean annual load of 2428 MTA, followed by the Sandusky (701 MTA) and Grand Ontario (346 MTA) rivers.

The TP outflow from Lake Erie via the Niagara River was estimated at 4834 MTA using a mean TP concentration of 27 µg P L<sup>-1</sup> based on measurements of the inflow to the Niagara River (Fig. 3; Table 6, B4 & B11). The annual loss of TP via the Niagara River plus the Welland Canal then amounted to 4997 MTA. Our Niagara River outflow flux of 4834 MTA is close to the mean value of 4791 MTA obtained by Hill and Dove (2021) who used data for the 2014–2018 period. Note that the TP concentrations measured in the waters of the Niagara River are significantly higher than the offshore TP concentrations of the eastern basin of Lake Erie (mean = 7.3 µg P L<sup>-1</sup>; Table B5; Appendix A7).

The removal of TP from Lake Erie's water column through sedimentation at the lake floor was comparable in magnitude to the watershed TP loading (Fig. 3; Tables 8, B6, B9 to B11): 807 MTA for Lake St. Clair and 9676 MTA for Lake Erie divided into 3188 MTA, 5032 MTA, and 1455 MTA for the western, central, and eastern basin, respectively. Expressed per unit surface area, the TP deposition fluxes were 0.97, 0.31, and 0.23 g P m<sup>-2</sup> yr<sup>-1</sup> in the western, central, and eastern basin, respectively, while in Lake St. Clair the rate was 0.72 g P m<sup>-2</sup> yr<sup>-1</sup> (Table 8). TP fluxes associated with changes in net water storage were small and insignificant relative to other inputs and output pathways (Tables 6, 8, B6 to B11; Fig. 3).

**Fig. 2.** (a) Surface areas of the sub-watersheds of the Lake St. Clair–Lake Erie system, including total area and respective areas in the United States and Canada. (b, c) Mean water budget of Lake St. Clair–Lake Erie system averaged over the 2003 to 2016 period, with (b) water fluxes in m³ s⁻¹ and (c) in km³ yr⁻¹. For the evaporative fluxes in b and c, the numbers in brackets are the original values which were adjusted to close the water budget. Numbers shown inside the boxes indicate the average annual water volumes in km³.

**Table 4**

Mean water volumes\* ( $V$ ), surface areas ( $A$ ), mean depths ( $Z_m$ ), water residence times ( $R_w$ ), total phosphorus (TP) residence times ( $R_p$ ), ratios of  $R_p$  to  $R_w$ , and standing stocks of TP in water column. All values are averages for the 2003–2016 period.

Segment	$V$ [km <sup>3</sup> ]	$A$ [km <sup>2</sup> ]	$Z_m$ [m]	$R_w$ [day]	$R_p$ [day]	$R_p/R_w$ [–]	TP standing stock in water column [metric tons]

35.	Lynn R., ON		172	2.2	5
36.	Big Cr., ON		741	9.7	26

The combined output estimates systematically exceeded the external inputs, especially for Lake Erie. To balance the TP budgets, 3563 and 220 MTA had to be added to the water columns of Lake Erie and Lake St. Clair, respectively. For Lake Erie's basins, the extra, in-lake sourced TP amounted to 495 MTA for the western basin, 795 MTA for the central basin, and 2273 MTA for the eastern basin (Fig. 3b; Table 8).

### 3.4. TP relative residence times

The mean hydraulic residence times ( $R_w$ ) ranged from 10 days for Lake St. Clair to 953 days (~2.6 years) for Lake Erie (Table 4), with 57 days for the western, 595 days for the central, and 301 days for the eastern basin. Mean TP residence times ( $R_p$ ) were systematically shorter than hydraulic residence times (Table 4):  $R_p$  was 8 days in Lake St. Clair and 312 days in Lake Erie, with 31, 180, and 101 days for the western, central, and eastern basins, respectively. The TP relative residence times ( $R_p/R_w$  ratios, Table 4) were 0.81 for Lake St. Clair, with values of 0.55 for the western basin, 0.30 for the central basin, and 0.34 for the eastern basin of Lake Erie. The  $R_p/R_w$  values for the St. Clair River and Detroit River channels were indistinguishable from 1.

## 4. Discussion

Earlier Lake Erie phosphorus mass balances, generally based on data for one or only a few years (Burns, 1976; Chapra, 1977; Chapra et al., 2016; Chapra and Dolan, 2012; Chapra and Sonzogni, 1979), have yielded valuable information on historical external loads and their role in eutrophication. The 14-year averaged, post-2000 TP mass balance for Lake Erie presented here extends these previous studies by capturing the long-term TP cycling, that is, at time scales significantly exceeding the hydraulic residence time of the overall lake system (Appendix A1). At such time scales, the assumptions of steady state water and TP budgets provide useful approximations to compare the magnitudes of TP inputs and outputs for the entire lake system as well as those for individual basins (Appendix A7). As we show, this comparison leads to the unavoidable conclusion that a significant fraction of the TP entering the water column comes from sources that are activated by in-lake processes. In the following sections, the TP budgets of Lake St. Clair and Lake Erie's three basins are discussed.

### 4.1. Lake St. Clair

Our estimate of the mean annual TP load to Lake St. Clair originating from Lake Huron (1862 MTA) is up to three times higher than some earlier proposed values (e.g., Dolan, 1993; Dolan and Chapra, 2012; Dolan and McGunagle, 2005; Maccoux et al., 2016), but in agreement with more recent assessments (Burniston et al., 2018; Scavia et al., 2019a, 2019b, 2020, 2022). According to our results, Lake Huron contributes 90% of the TP load carried by the St. Clair River, with the remaining 10% coming from St. Clair River's direct watershed. It further

**Table 6**

Mean annual water and phosphorus budgets for the Lake St. Clair–Lake Erie system for the 2003 to 2016 period.

implies that TP sourced from Lake Huron represents the largest fraction (61%) of the total external TP input to Lake St. Clair, with the latter estimated at 3042 MTA. In comparison, 2447 MTA leave Lake St. Clair and flow into the Detroit River. Thus, about 19% of the external TP load

to Lake St. Clair is retained in the lake (Table 6), which agrees with previous estimates (17%, Bocaniov et al., 2019; 21%, Scavia et al., 2019b), hence illustrating the important role Lake St. Clair plays in moderating the TP input into the western basin of Lake Erie.

**Fig. 3.** (a) Mean TP fluxes (2003 to 2016) in metric tonnes per annum (MTA) for the major segments of the Lake St. Clair–Lake Erie system, with (b) showing additional details for the three basins of Lake Erie. Numbers shown inside the boxes indicate the average annual standing stocks of TP in MTA. Summed loadings may not add up exactly due to rounding errors.

Lake St. Clair's mean internal TP load is estimated at 220 MTA (Fig. 3a; Table 8). While this is about one order of magnitude less than the external TP load, it is still a significant input considering the water column TP standing stock of 69 MT (Table 4). A priori, a large internal TP load may not be expected given that Lake St. Clair is shallow and well mixed. Thus, a high internal P loading from the lake floor driven by bottom water hypoxia (e.g., Parsons et al., 2017) would seem unlikely. Other mechanisms, however, might be involved. For instance, the Thames River discharge is extremely low in summer (Bocaniov et al., 2019) and the downstream river reach itself may stratify vertically for a few days to a week or longer. The river is located in a fertile fluvial valley and carries high loads of fine-grained sediments enriched with nutrients (Stone and Saunderson, 1992, 1996). Nürnberg and LaZerte (2015) have suggested that this material can create a high sediment oxygen demand and generate hypoxic episodes that may release highly bioavailable P from the river sediments, which is then transported to the lake. Furthermore, mixing of bottom sediments by shear stress can release pore water and contribute to internal P loading as well (Tammgeorg et al., 2022).

Another potential TP source is loading from the St. Clair River delta.

The lower reach of the St. Clair River empties into the lake through a unique “burrowing” delta that slowly propagates downstream causing erosion and lakeward transport of older sediment (Thomas et al., 2006). The eroded material with the associated P enters the lake but is not captured by the water quality monitoring stations in the St. Clair River because these stations are located upstream of the delta (see Fig. 1, water quality monitoring stations #3 and #4). Our mass balance results therefore reinforce the need to consider internal P loading mechanisms other than the “classical” redox-sensitive benthic P recycling from recently deposited sediments.

#### 4.2. Western Basin

The external TP load entering Lake Erie's western basin via the Detroit River (3112 MTA; Tables 6 & 8; Fig. 3) is of similar magnitude as the combined external load supplied from the western basin's direct watershed plus atmospheric deposition and direct groundwater input (3148 MTA). The net internal TP load of the western basin is estimated at 495 MTA (Tables A1 & 8; Fig. 3b). In the western basin, a major internal P loading pathway is likely dissolved P efflux from the lake

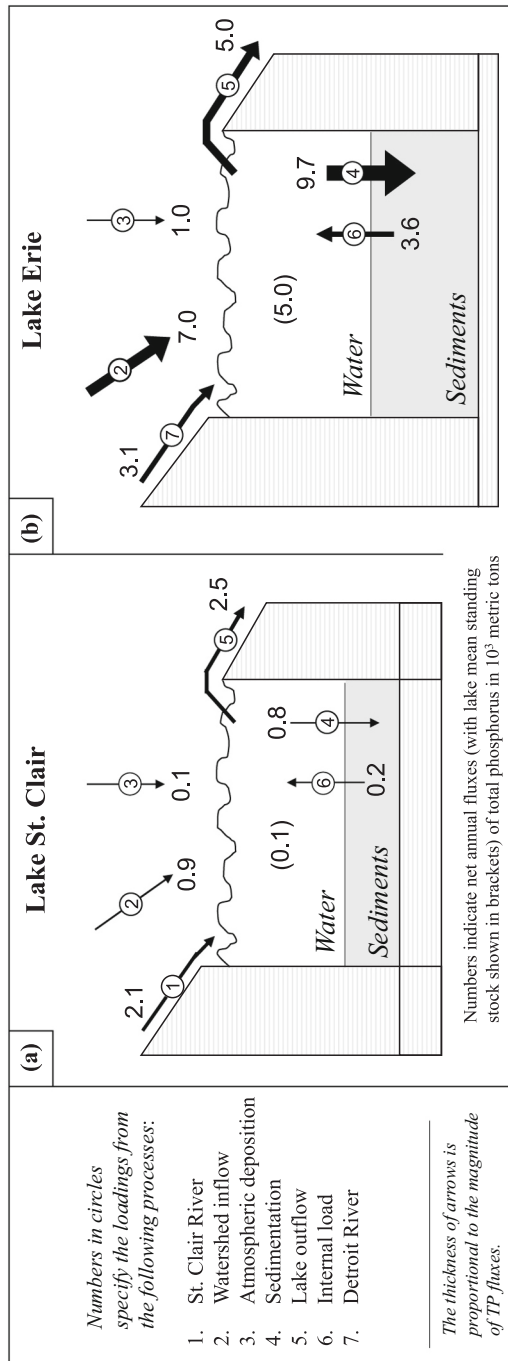

Fig. 4. Simplified conceptual diagram of mean total phosphorus (TP) inputs and outputs (in 1000s of MTA) for Lake St. Clair (a) and Lake Erie (b) for the period of 2003 to 2016 based on the results presented in Fig. 3.

bottom sediments under reducing conditions (Gibbons and Bridgeman, 2020; Matisoff et al., 2016; Parsons et al., 2017) during intermittent bottom water hypoxia (Jabbari et al., 2019, 2021; Rowe et al., 2019). Nonetheless, other processes may also be involved, for example, the supply of sediment-bound P via the Detroit River (Colborne et al., 2019).

Matisoff et al. (2016) estimated the gross internal P load to the western basin in 2013 and 2014 to be around 593 MTA (range: 378 to 808 MTA; Table A1, ID#1), close to our 495 MTA estimate (Fig. 3b). Phosphorus released from the bottom sediments is expected to be rapidly incorporated into the food web, because intermittent hypoxia that usually occurs from June to September (Jabbari et al., 2019) overlaps with the formation of cyanobacterial blooms in June to early October (Sayers et al., 2019). Thus, in addition to the Maumee River's spring TP loads that drive most cyanobacterial bloom models (Bertani et al., 2016; Scavia et al., 2021; Stumpf et al., 2016), the hypoxia-induced internal TP load could provide an additional bioavailable P supply sustaining algal growth during summer-early fall, as proposed by Matisoff et al. (2016). This explanation is also consistent with Ho and Michalak (2017) and Scavia et al. (2023) who reported improved model performance when the cumulative P load from previous years was added as a surrogate for the P internal load.

Sediments in the western basin have been shown to be a source of biologically available P and chemically reduced forms of N (e.g.,  $\text{NH}_4$ ) that can contribute to support the non-nitrogen-fixing cyanobacterial HABs (Microcystis blooms) typical of the western basin (Boedecker et al., 2020). The estimated magnitude of the internal TP loading in the western basin, however, is small compared to the basin's external load (495 versus 6256 MTA; Table 8). Thus, while the external TP load is undeniably the main driver of HABs in the western basin, internal loading from bottom sediments could be an additional, subtler, factor modulating HAB dynamics in the basin – a role that deserves to be investigated further.

#### 4.3. Central Basin

Similar to the western basin, the TP loading to Lake Erie's central basin from the upstream lake segment (3563 MTA) is of comparable magnitude to that supplied from the direct watershed plus atmospheric deposition and direct groundwater input (3167 MTA). The Central Basin also exhibits one of the largest known freshwater hypoxic zones in the world with a maximum extent of up to 12,000  $\text{km}^2$  (Zhou et al., 2013; Bocaniov and Scavia, 2016; Bocaniov et al., 2016, 2020). Hence, among Lake Erie's three basins, the central basin might be expected to be most impacted by internal TP loading from sediments overlain by anoxic bottom waters.

Based on our mass balance calculations, net internal TP loading contributes 795 MTA, which fall in the range of 300 to 2400 MTA proposed by Paytan et al. (2017) (see Nürnberg et al., 2019, for a critical analysis of this range). Some recent studies have reported much larger benthic P effluxes for the central basin, between 10,000 and 11,000 MTA (Anderson et al., 2021; Wang et al., 2021). The reason for the large differences between the latter estimates and ours is not certain but may reflect a less efficient incorporation of P released from the bottom sediments into the food-web compared to the western basin. In turn, this could reflect the restricted upward transfer of the released P to the photic zone during summer when the water column is stratified. In addition, following fall turnover and the return of oxygenated conditions, dissolved phosphate may be scavenged by oxidized Fe phases settling to the lake floor (Burns and Nriagu, 1976; Manning et al., 1984). Not unexpectedly, this suggests significant differences in the fate of the internal P load released during the short-lived intermittent hypoxic events in the shallow western basin and that produced by the longer-duration stratification and hypolimnetic hypoxia of the deeper central basin.

**Table 8**

Segment-specific total (MTA) and areal ( $\text{g P m}^{-2} \text{yr}^{-1}$ ) rates of total phosphorus (TP) inputs and losses: watershed inputs ( $W$ ); inputs and losses due direct ground water discharge, water consumptive use, and change in water storage ( $GR$ ,  $CU$  and  $\Delta V$ , respectively); over-lake total atmospheric deposition ( $A$ ); inter-segment exchanges ( $IB$ ); internal loads ( $L$ ), and sedimentation losses ( $S$ ). See Table 7 for the segment full names.

#	Rates (units)	Loads / Losses	SCR	LSC	DR	WB	CB	EB	LE	LES

**Table 9**

Total phosphorus (TP) concentrations ( $\text{mg P L}^{-1}$ ) in ground water monitoring wells within 8 km of lake shorelines for the period of 2002 to 2019.

Location	# of wells	$N$	Mean	$SD$	Median
Lake Erie Basin, including:	19	179	0.068	0.137	0.020
- Western Basin	6	68	0.026	0.069	0.012
- Central Basin	8	69	0.115	0.173	0.032
- Eastern Basin	5	42	0.060	0.133	0.020

Note:  $N$ , number of observations; *Mean*, mean value, *SD*, standard deviation; *Median*, median value; for groundwater well locations and well characteristics see Table A9.

#### 4.4. Eastern Basin

The eastern basin is the coldest and deepest of Lake Erie's three basins. The largest fraction of the external TP loading to the eastern basin is supplied from the upstream central basin (59%, 2485 MTA) with a somewhat smaller contribution from the watershed, atmospheric deposition plus groundwater inputs (41%, 1699 MTA). In contrast to the other two basins, the eastern basin does not experience substantial bottom water hypoxia, nor is it affected by large cyanobacterial blooms. The estimated internal TP load for the eastern basin (2273 MTA; Fig. 3b), however is the largest of the three basins. In contrast to the two other basins of Lake Erie, the net internal TP load of the eastern basin exceeds the basin's combined external input from its watershed and airshed.

The "classical" internal P loading mechanism where dissolved P is released from recently deposited sediments in response to bottom water hypoxia cannot explain the inferred large internal TP load. Not only are hypoxic bottom water conditions relatively rare but the estimated P settling rate in the eastern basin is also the lowest of the three basins ( $0.23 \text{ g P m}^{-2} \text{yr}^{-1}$ , Section 3.3). Thus, other in-lake processes must be responsible for generating the internal TP loading of the eastern basin. These may include shoreline erosion and resuspension, not unlike the delivery of Lake Huron sediment-bound TP to Lake St. Clair (see Section 4.1), as well as the nearshore phosphorus shunt caused by the filtering

activity of invasive dreissenid mussels (Bocaniov et al., 2014; Hecky et al., 2004). Chapra and Dolan (2012) further suggested that apart from shoreline erosion and mussel grazing other input pathways may be involved, for example nearshore P assimilation during benthic macroalgal blooms (e.g. *Cladophora*) and the subsequent nearshore transport of biomass-associated P to the eastern basin's outlet after bloom collapse. These processes would result in the preferential P enrichment of the coastal waters of the basin, which subsequently flow out of Lake Erie via the Niagara River and Welland Canal. While speculative, this explanation would also account for the relatively high TP concentrations measured at the mouth of the Niagara River ( $27 \mu\text{g P L}^{-1}$ , Section 3.3).

#### 4.5. Relative TP residence times

The relative TP residence times ( $R_p/R_w$ ) provide a measure of the role in-lake processes play in controlling the TP standing stock of a water body. If TP behaves as a conservative tracer, then  $R_p/R_w$  is equal to 1 (Janus and Vollenweider, 1984). This is the case for both the St. Clair River and the Detroit River (Table 4). All P entering these channels is rapidly ( $< 1$  day) transferred to the downstream lake segment with negligible in-channel processing. In the lake basins, however,  $R_p/R_w$  values deviate from 1. The  $R_p/R_w$  value for Lake St. Clair ( $R_p/R_w = 0.81$ ) is still relatively close to 1, in line with the relatively short water residence time and, hence, limited time for extensive P cycling in the lake basin. The much lower overall value for Lake Erie ( $R_p/R_w = 0.33$ ) reflects the much longer water residence time (2.6 years; Table 4) that enables a large in-lake retention of P. Of the 11,116 MTA combined external loading to the three basins of Lake Erie, only 4997 MTA exit the lake via the Niagara River and Welland Canal. Burial of P in sediments accounts for almost all the missing 6119 MTA, with only 0.2% attributed to the change in water column storage and consumptive use.

#### 4.6. Some implications

The important role internal nutrient loads play in modulating the trophic state of lake ecosystems is well recognized (Boström et al., 1982;

Ekholm et al., 1997; Ho and Michalak, 2017; Isles et al., 2015; Markelov et al., 2019; O'Connell et al., 2020; Orihel et al., 2017; Soranno et al., 1997; Yang et al., 2020). The budget estimations presented here imply that this is also the case for the large Lake St. Clair–Lake Erie system. Our estimates suggest that internal P supply to the water column represents close to a quarter of the total (external plus internal) P input to the entire system. It explains why models of algal blooms in the western basin that include a surrogate for the internal P load (Ho and Michalak, 2017; Scavia et al., 2023) may perform better compared to existing statistical (e.g. Bertani et al., 2016; Stumpf et al., 2016) and mechanistic ecological models that do not account for internal P loading.

## Declaration of Competing Interest

None.

## Data availability

Datasets used within this study can be obtained from public sources described in Data and Methods section of this paper. Additionally, data are also openly available from the Federated Research Data Repository (FRDR) website at DOI:10.20383/102.0695

## Acknowledgements

We gratefully acknowledge the help of Ngan Diep of the Ontario Ministry of the Environment, Conservation and Parks (MECP) and scientists at Environment and Climate Change Canada (ECCC), especially Alice Dove, Sean Backus, Ram Yerubandi Rao, Daryl McGoldrick, Sarah Gewurtz, Brad Hill, Mohamed Mohamed, David Depew and Debbie Burniston, for providing data on measured phosphorus concentrations in the Canadian tributaries to Lake Erie. The authors also thank Nandita Basu, Homa Kheyrollah Pour and Igor Markelov of University of Waterloo for their support of this work, as well as the United States Great Lakes National Program Office (GLNPO) for their lake nutrient concentration data. We sincerely appreciate all valuable comments and suggestions from two anonymous reviewers and Dr. G. K. Nürnberg, which helped us improve the quality of the manuscript. This work is part of the Lake Futures project within the Global Water Futures (GWF) program and supported financially by the Canada First Research Excellence Fund (CFREF).

## Appendix. Supplementary Data A and B

Supplementary data to this article can be found online at <https://doi.org/10.1016/j.ecoinf.2023.102131>.
